Abstract

This paper presents results for five separately estimated sets of participation and wage equations. The Australian working-age population is divided into sole parents, single men, single women, married men and married women. The approach in this paper takes the censoring of labour supply observations at 50 hours per week into account. The results for the wage equations are as anticipated with education, work experience and age increasing the expected wage. As expected, allowing for the censoring of labour supply reduces the predicted wage levels, particularly for married men who are most likely to work 50 hours or more.

1 Introduction

This paper reports estimates of wage functions for a number of demographic groups in Australia, using pooled information from the 1994/95, 1995/96, 1996/97 and 1997/98 Surveys of Income and Housing Costs (SIHC). This is an extension from a previous paper using 1995 and 1996 SIHC data (Creedy et al., 2001). More importantly, in addition to the extra years of data, the model used in this paper accounts for the censoring of labour supply information at 50 hours that occurs in the SIHC data.

The aim of estimating wage equations often is to impute wage rates for those who are not currently working, so that they can be used in labour supply models.¹ In this paper the wage equation is estimated separately, but a similar approach to the one taken in this paper could be followed when estimating wage and labour supply simultaneously.

The imputation of wage rates is complicated by the fact that wage equations should ideally contain variables, such as industry and occupation, which are not observed for non-workers (for the same reason that wage rates are not available). These variables are major determining factors of wage rates. This paper therefore follows the same approach as a previous paper on this topic (Creedy et al., 2001). As in other articles, the estimation procedure corrects for the sample selection bias that would arise from the fact that only the wage rates of those currently working are observed using the standard Heckman procedures (Heckman, 1979). Earlier Australian wage functions were discussed for example by Miller and Rummery (1991), Murray (1996), Kalb (2000), and Creedy et al. (2001).

The results show that after accounting for censoring, lower wage rates are predicted. This may, for example, be important when these wage equations are used to impute wage rates in labour supply models. In addition, the equation could be used to impute wages for those working 50 hours or more, allowing for the uncertainty of hours worked but incorporating the available information. In the latter case the prediction of the wage

¹ Many tax policies are specially designed in an attempt to stimulate an increase in labour supply. There would therefore be little value in restricting analyses to those currently working, thereby excluding non-participants whose participation decision may be influenced by taxes and transfers. Labour supply analyses require an individual-specific budget constraint, so a wage rate must be assigned to non-workers.

would be conditional on it lying in the observed range.

The standard selection model is described briefly in section 2. The data are described in section 3. Estimates of the wage equations are reported in section 4. The problem of assigning wage rates to non-workers and the prediction of wage rates for some hypothetical individuals are discussed in section 5. Brief conclusions are in section 6.

2 The Statistical Model

The estimation of wage equations involves a system of two correlated equations, the first of which determines selection (employment) using a probit equation, while the second determines wage rates, conditional on employment. The correlation between the two equations accounts for the possible selection into work of those with higher wage rates. The wages of workers may therefore not represent the wages of non-workers. However, the inclusion of an additional term in the wage equation indicating the tendency to participate can correct for this.

Each individual's observed employment outcome is regarded as being the result of an unobservable index of tendency to participate in the labour force and employability, E_i^* , which varies with observed personal characteristics, z_i . The variables included in z may include both supply and demand side variables. Hence:

$$E_i^* = z_i' \gamma + u_i \quad (1)$$

where u_i is assumed to be independently distributed as $N(0, 1)^2$. The realisation of E_i^* determines whether the individual is employed ($E_i = 1$), or unemployed or out of the labour force ($E_i = 0$), such that:

$$E_i = \begin{cases} 1 & \text{if } E_i^* > 0 \text{ with prob. } \Phi(z_i' \gamma) \\ 0 & \text{if } E_i^* \leq 0 \text{ with prob. } 1 - \Phi(z_i' \gamma) \end{cases} \quad (2)$$

where $\Phi(z_i' \gamma)$ is the standard normal distribution function evaluated at $z_i' \gamma$. The associated normal density function is denoted $\phi(z_i' \gamma)$. The parameters of (2) can be consistently estimated by a standard probit model; see Maddala (1983). Having

² As there is no information about the scale of E_i the variance of u cannot be identified and is therefore set equal to unity.

estimated (2), an estimate, $\hat{\lambda}_i$, of the inverse Mill's ratio for a working individual i is obtained using:

$$\hat{\lambda}_i = \frac{\varphi(z_i' \hat{\gamma})}{\Phi(z_i' \hat{\gamma})} \quad (3)$$

Let w_i denote the logarithm of the wage rate and x_i a vector of characteristics of individual i . The regression model is written as:

$$w_i |_{E_i=1} = x_i' \beta + \varepsilon_i \quad (4)$$

The u_i from equation (1) and ε_i are assumed to be jointly normally distributed as $N(0, 0, 1, \sigma_\varepsilon^2, \rho)^3$. In order to avoid selectivity bias, a correction term is added to (4):

$$w_i |_{E_i=1} = x_i' \beta + \rho \sigma_\varepsilon \hat{\lambda}_i + v_i \quad (5)$$

Equation (5) takes into account the correlation between u_i and ε_i . It can be seen that the variance of v_i , σ_i^2 , is heteroscedastic, since:

$$\sigma_i^2 = \sigma_\varepsilon^2 (1 - \rho^2 \delta_i) \quad (6)$$

where:

$$\delta_i = \lambda_i (\lambda_i + z_i' \gamma) \quad (7)$$

Efficient estimation of this model is carried out using the convenient two-step procedure of first estimating the probit model for the employment probability and calculating the predicted value for the inverse Mill's ratio. The predicted Mill's ratio is then used in the wage equation. Greene (1981) shows how to calculate the corrected standard errors.

In the SIHC, described below, for individuals working 50 hours per week or more, the exact hours worked are not observed. In these cases only the maximum possible value is known of the dependent variable w_i , that is, the wage rate has to be smaller than the total income from wages and salaries divided by 50. Given that people are extremely unlikely to work more than 100 hours per week, the total income from wages and

³ The covariance between u_i and ε_i is thus $\rho \sigma_\varepsilon$.

salaries divided by 100 is used as a lower boundary for the wage rate. Estimating the wage equation by the Maximum Likelihood method, instead of the usual contribution of an observation to the likelihood function of:

$$\ln L_i = \ln \Pr(v_i = w_i - x_i'\beta - \rho\sigma_\varepsilon\hat{\lambda}) = -0.5 \ln(2\pi) - \ln \sigma_i - \frac{(w_i - x_i'\beta - \rho\sigma_\varepsilon\hat{\lambda})^2}{2\sigma_i^2} \quad (8)$$

the contribution, when only the range of the wage is known, becomes:

$$\begin{aligned} \ln L_i &= \ln \Pr(w_{i,\min} - x_i'\beta - \rho\sigma_\varepsilon\hat{\lambda} \leq v_i \leq w_{i,\max} - x_i'\beta - \rho\sigma_\varepsilon\hat{\lambda}) \\ &= \ln \left[\int_{w_{i,\min} - x_i'\beta - \rho\sigma_\varepsilon\hat{\lambda}}^{w_{i,\max} - x_i'\beta - \rho\sigma_\varepsilon\hat{\lambda}} \frac{1}{\sigma_i \sqrt{2\pi}} \exp\left(-\frac{(t)^2}{2\sigma_i^2}\right) dt \right] \end{aligned} \quad (9)$$

where

$w_{i,\max}$ is the maximum possible value for the wage rate, and

$w_{i,\min}$ is the minimum possible value for the wage rate.

By using interval regression in these cases (and including a range rather than one value for the dependent variable), overestimation of the wage rate is avoided and the uncertainty associated with the wage rate for people working more than 49 hours is included in the estimation.

3 The Data

The data used in this analysis are taken from the 1994/95, 1995/96, 1996/97 and 1997/98 Surveys of Income and Housing Costs, available from the ABS in the form of confidential unit record files (CURFs). The survey collects information on the sources and amounts of income received by persons resident in private dwellings throughout Australia, along with data on a range of characteristics of income units and individuals. The survey is continuous with around 650 households interviewed every month during the financial year. In the surveys from 1994/95 to 1997/98, information is available respectively for 13827, 14017, 14595 and 13931 individuals over the age of 15.

Earlier Surveys of Income and Housing Costs (or Income Distribution Surveys as they were called then) were carried out, but the 1994/95 survey is the first to provide published data on the precise hours worked (up to 50 hours per week) by each individual worker in the sample; earlier surveys contain only grouped information on labour supply, divided into broad hours groups. The details of hours worked are

required for the calculation of wage rates, obtained for each individual as the ratio of total earnings to hours worked. Hence the following analysis ignores the possibility that individuals may obtain overtime premiums, or may work in more than one job. Where individuals worked 50 hours or more⁴, the exact wage rate is unknown. It is only known that the wage must be lower or equal to the total earnings divided by 50. The estimation procedure takes this into account by using an interval regression when the recorded hours worked equals 50. In this interval regression, we assume that the maximum number of hours of labour supply is 100 per week. As a result the wage must be higher than the total earnings divided by 100.

The majority of the data used as explanatory variables were recoded as zero-one dummy variables. To keep all the variables to a similar scale all of the non-wage income variables were divided by 1000 while age was divided by 10. Any individuals with inconsistent observations on income from wages or salaries and hours worked, that is positive earnings for zero hours or zero earnings for positive hours, are excluded from the wage equation (as sensible wage rates cannot be calculated for them). However these observations do remain in the participation equation assuming that we correctly observe whether or not they are in the work force. As the emphasis of the analysis is on obtaining results to be used in labour supply analysis for people of working age, individuals over 65 years are excluded from the sample. Furthermore, groups such as the disabled and those in full-time education are excluded, because they are unlikely to participate in the labour force and the factors determining their participation decision would be quite different from other people of working age. Finally, the self employed are omitted from the sample, because their decision to work an additional hour cannot be linked to the wage rate for that additional hour, which is crucial in the labour supply estimation for the wage and salary earners⁵.

⁴ Table A.1 shows the proportion of people in the different demographic groups, who work 50 hours or more. Except for sole parents, a substantial number of people fall into this category.

⁵ In the four surveys used, there were 1035 people either at school or studying full-time. There were 18 unpaid voluntary workers and 283 individuals permanently unavailable for work. Also, there were 8141 individuals over the age of sixty-five. There were 4978 self-employed persons.

The four surveys were pooled⁶ and the sample was divided into five demographic groups. These are: sole parents; single females without dependents; single males without dependents; married females; and married males. Summary tables of sample characteristics are provided for each demographic group in the Appendix. It was not possible to estimate separate equations for sole mothers and sole fathers, given the small number of sole fathers in the sample⁷.

Table 1 presents the average real wage rates across the four years for the five demographic groups. Here it can be seen that, once wage inflation has been accounted for, average wages do not seem to change systematically between the various survey years. In estimation, we include year dummies in the wage equation to check more formally for systematic differences over time.

Table 1: Average real wage rates for 1994/95 to 1997/98, inflated to May 1998 level

	1994/95	1995/96	1996/97	1997/98
Sole parents	14.79	15.56	16.51	15.66
Single females	14.08	13.76	14.04	14.42
Single males	14.64	14.69	15.03	15.10
Married females	15.96	16.00	15.82	15.95
Married males	18.70	18.76	19.02	18.94

Examples of distributions of the logarithms of observed hourly wage rates for the five demographic groups are shown in Figures 1 to 5. These are based on May 1998 wages and the censoring of labour supply at 50 hours per week is not taken into account⁸. The histograms suggest that these distributions are approximately lognormal, although they are slightly more peaked than the corresponding normal distributions with the same mean and variance. Individuals reporting wage rates lower than \$4 an hour or greater than \$100 an hour are considered outliers and are omitted from the wage equation.

⁶ All wage rates are increased to the values they would have had in 1998 using indices derived from average weekly earnings for males and females respectively and all income from other sources is inflated with the appropriate consumer price index to obtain the value it would have had in 1998.

⁷ There were 194 male sole parents, compared with 1593 females.

⁸ That is, when the wage rate is calculated from weekly earnings and the weekly hours worked no account is taken of the fact that for people working 50 hours or more the exact weekly hours are unknown. Instead, wages for this group are calculated by dividing earnings by 50.

These observations remain in the participation equation. As expected, the graphs show that the modal wage rate is higher for men than for women.

4 Empirical Results

This section presents the main empirical results. The results for the selection equations are presented in the Appendix. The estimated wage equations, conditional on being in employment, are reported for each demographic group in Tables 2, 3 and 4. The results here look quite similar to the results in Creedy et al. (2001). The main difference between the two models is that, in the version presented here, some additional explanatory variables on recent work experience are included. The sample sizes are, for married women, married men, single women, single men and sole parents respectively 7434, 9513, 3398, 4459 and 836. The inverse Mill's ratio has the expected sign for married women and sole parents only, that is for these two groups the parameter is significant and positive. The inverse Mill's ratio is insignificant for married men and single women and significantly negative for single men. The interpretation of negative inverse Mill's ratios in this context was discussed by Ermisch and Wright (1994)⁹. The results on this coefficient are not comparable to the results in Creedy et al. (2001) since a different selection equation was estimated.

⁹ Miller and Rummery (1991) found a positive value for women and a negative value for men. They also review results found in previous Australian studies. They do not distinguish between single and married men and women. Murray (1996) found a positive value for mothers (single and married) and Kalb (2000) found a positive value for married women and a negative (insignificant) value for married men.

Here all models are presented with the Mill's ratio included. However to impute wages for non-workers, the equations for married men and singles are re-estimated using the interval regression specification without the selection correction. For these groups the Mill's ratio is not significant at the 5-per cent level.

To ensure that changes over time in the proportion of people not working (which combines those in unemployment and out of the labour force) and the proportion in employment¹⁰ did not affect the estimated results, a wage equation including year

¹⁰ See Table A.1 for the proportion of respondents in the different labour market states in each of the survey years.

dummies for each of the survey years has been estimated. These dummies turned out to be insignificant, indicating that after taking into account the changes in average wage rates for men and women separately, wages do not appear to differ significantly over the years.

The coefficients more or less display the expected variation of wage with age, that is wage rates generally increase with age up to people's early forties, after which they decline again with age. The exception is the sole parents group, where no effect from age is found. The age effect is more important for singles than for couples.

There is a considerable amount of difference in wage rates between occupations and educational qualifications. Wage rates of professionals, paraprofessionals, and clerical or salespersons are significantly higher than for trades persons or labourers across all groups. As expected, the wage level is highest for professionals, followed by paraprofessionals and then clerical or salespersons. Wage rates also tend to increase with the level of educational qualification across all groups. Generally, people educated at university level have the highest wages, although for single men a vocational education seems just as beneficial. Sole parents with a diploma receive considerably lower wages compared to sole parents with a postgraduate or undergraduate degree, followed by sole parents with a vocational qualification. The significance of the interaction term between age and education level (distinguishing between university level or less) indicates that the effects of age and education are not completely independent of each other. For single women and married couples the coefficient indicates that people with a university degree, have wages that increase more with age than people without a university degree. This might indicate that work experience results in more wage growth for people with a higher education level.

Work experience in the previous financial year has a positive effect on current wage rates. However, the number of months in employment out of the last seven has little, and sometimes even a negative, effect; only for married women and sole parents is the effect positive and significant. The latter group, in particular, has a wage premium for recent work experience, but on the other hand, the effect of work experience in the last financial year is smaller than for other groups (and insignificant).

Couples living in NSW experience higher wage rates than those living in the other states, with the exception of those residing in the Territories who receive even higher wages; residents of the ACT form the larger part of this category. People living in capital cities are paid higher wage rates than their counterparts living in other areas of the country. Wage rates of married women and married or single men are higher in all industries compared with the agriculture/forestry industry (the reference industry). For single women and sole parents only the wage rates in mining, utilities, transport and communication are significantly higher. People in the mining and utilities industries generally have the highest wages, for men and sole parents the difference between these and other industries is particularly high. The differences in wage rates between industries are smallest for married women.

There seems to be little effect on wages depending on the country of origin. Only immigrants from Asia earn significantly lower wages if they are in the groups of sole parents or married men or women. Married men from America and Africa earn less than those born in Australia. The effects for singles are insignificant and smaller in size. This perhaps reflects a difference in the effect of being an immigrant between younger (who are more likely to be single) and older age groups.

Female sole parents earn significantly less than male sole parents. Comparing the size of the coefficient with the difference in the constant terms in the wage equations for married men and women and in the equations for single men and women, it appears that the gender difference in wages for sole parents is similar to the gender difference for the other groups.

Finally, the estimated standard error (σ_ϵ) has a similar size over all the demographic groups. It is largest for married men, indicating that for this group a larger proportion of the differences in wage rates has not been explained by the variables included in the equation. The standard error is smallest for single women, however, the differences between groups are rather small.

5 Wage Predictions

This section considers the question of how a wage rate may be assigned to unemployed individuals. In the simple case where the selection and wage equations contain a common set of variables, consider first the conditional mean log-wage rate, for an individual with given characteristics. For those who are employed, this is given by:

$$E(w_i | E_i=1) = x_i' \hat{\beta} + \hat{\rho} \hat{\sigma}_\varepsilon^2 \hat{\lambda} \quad (10)$$

Imputed wage rates for those who are unemployed can be obtained using the expression:

$$E(w_i | E_i=0) = x_i' \hat{\beta} - \hat{\rho} \hat{\sigma}_\varepsilon^2 \frac{\phi(z_i' \hat{\gamma})}{1 - \Phi(z_i' \hat{\gamma})} \quad (11)$$

The use of the conditional mean log-wage is perhaps the most obvious choice for the predicted wage. It is also possible, for example, to take a random draw, for each individual, from the relevant conditional distribution. Indeed, in labour supply analyses there is no necessity to be restricted to using observed wage rates for those employed in the sample period: it would also be possible to take random draws from the relevant conditional distributions.

In the present context, the expression in (11) cannot be used without modification because some variables used in the estimation of the wage functions are not available for non-workers. In addition to the wage rate, neither the occupation nor the industry of non-workers is known. Although these variables could not be included in the selection equations, they were included in the wage equations because of their demonstrated importance in wage determination. An alternative predictor for non-workers is simply (11) with the dummy variables for occupation and industry replaced by the sample proportions in the different categories. Since it is likely, that the distribution across occupations differs between the employed and the unemployed workers, extraneous information on unemployment rates within the various occupation and industry groups are used to assign proportions within occupation and industry groups to the non-workers (see Table A.4). For a complete discussion of this approach see Creedy et al. (2001).

5.1 Marginal effects

This subsection provides selected examples of the extent to which a person's wage rate may change given a change in their observable characteristics.

Consider first what the impact of postgraduate qualifications is on the wage rates of individuals. A typical sole parent or married female with a postgraduate degree is expected to be offered a wage rate which is about 31 per cent higher than for those without post secondary qualifications¹¹. Single females without dependents and married men can expect a return from postgraduate qualifications of about 12 per cent, while single males without dependents exhibit the lowest (and insignificant) wage premium for a postgraduate qualification with wage rates only 11 per cent higher.

Second, let's consider what impact living in a capital city has on the wage rate of individuals. Wage rates are higher across all five demographic groups for individuals residing in the capital city of their State. Single males experience the smallest effect on their wage rates with less than a three per cent increase by living in a capital city. Sole parents, single females and married males and females all have wage rates which are between four and six per cent higher in capital cities.

Finally, consider what the impact of age is on the wage rates of individuals. To calculate the age effect, we need to take into account the coefficients of age and age squared. In addition the effect depends on the starting age. The effect for married men is an increase of 7.7¹² per cent for a ten-year increase in age from 25 to 35 years and a 3.0 per cent increase for a ten-year increase from 35 to 45 years. This reflects the turnaround point in people's early forties, from an increasing wage rate with age to a decreasing wage rate with age.

¹¹ This value is calculated by using the following formula: $[\exp(\text{relevant coefficient}) - 1] \times 100\%$. In this example that is: $[\exp(0.268) - 1] \times 100\% = 30.7\%$.

¹² The formula used in this calculation is $[\exp(\text{coefficient of age} + \text{coefficient of age squared} + 2 * (\text{age at start} / 10) * (\text{coefficient of age squared})) - 1] \times 100\%$. In this example that is: $[\exp(0.206 - 6 * 0.022) - 1] \times 100\% = 7.7\%$.

5.2 Selected Examples of Predicted Wages

This subsection provides selected examples of predicted wages obtained when unemployed individuals are assigned the sample occupation and industry characteristics.

Consider first a female unemployed sole parent with the following characteristics: aged 32 years; vocational qualification; no recent work experience; separated/widowed from a previous relationship; European born; residing in ACT/NT; with no other income unit income; with two dependent children, one aged between 5 and 9 years and the other between 10 and 15 years; living in 'other tenure'. The predicted or imputed wage obtained using (employed) sample averages for industry and occupation groups is found to be \$9.87 per hour. We can also calculate a predicted wage using the model, which does not account for the censored labour supply observation¹³. This is \$10.17, which is only slightly higher than the specification accounting for the censoring of labour supply over 49 hours. There are relatively few sole parents working long hours, so one would not expect a large difference in the outcomes from the two specifications.

Second, consider a single female without children; never married; aged 22 years; Australian born; residing outside the Sydney metropolitan region in NSW; with a vocational qualification; no recent work experience; living in 'other tenure' with no other income. The imputed hourly wage is found to be \$10.48 (\$10.63 in the model which does not account for censoring in labour supply).

Third, consider an unemployed single male without children; never married; aged 22 years; vocational qualification; no recent work experience; Australian born residing outside the Brisbane metropolitan region in Queensland; in rented accommodation. The imputed wage is \$11.06 (\$11.56 in the model which does not account for censoring in labour supply).

¹³ The coefficients for the models not accounting for the censoring of labour supply at 50 hours can be found in Tables A.8 to A10.

Fourth, consider an unemployed married female: aged 42 years; with one dependent child aged over 15 years; European born; residing in Perth; without formal educational qualifications; no recent work experience, but worked during last financial year; partner has vocational qualification but is currently not employed; other income is \$25 per week; owns home outright. The basic imputed wage is \$12.32 per hour (\$12.70 in the model which does not account for censoring in labour supply).

Finally, consider an unemployed married male: aged 47 years with five dependent children (three of which are aged 5 to 9 years, two are aged 10 to 15 years); European born; residing in Melbourne; with a diploma; no recent work experience, but worked during last financial year; partner has no formal qualifications and is currently not employed; no other income; owns home outright. The basic hourly rate is \$21.44 per hour. In a model not taking into account the censoring of labour supply over 49 hours per week this would have been \$25.22. The difference for married men between the two specifications is much larger than for the other groups, because a large proportion of the group of married men falls in the category, which works 50 hours or more. Thus accounting for censoring of labour supply is more important in this group.

To explore the sensitivity of the results to the choice of upper boundary for the range of possible labour supply, the wage equations have been re-estimated with the maximum labour supply set to 75 hours instead of 100 hours.¹⁴ These alternative models have been used to predict the wage for the same hypothetical persons as above. We find that changing the upper bound from 100 to 75 hours increases the expected wage somewhat but the difference between these two specifications is much smaller than between the uncensored specification and the 75 hours upper bound specification. For example for sole parents the predicted wage becomes \$9.97, which is 10 cents higher than the predicted wage when using an upper bound of 100 hours and 20 cents lower than in the model where no allowance is made for the censoring. The effect is smallest for single women at \$10.52, which is only 4 cents higher than for the alternative upper bound and 11 cents lower than in the model not allowing for censoring. As expected the effect is highest for married men. At \$ 22.74, it is \$1.30 higher than for the alternative upper bound and \$2.48 lower than the results from the model not allowing for censoring.

¹⁴ The tables with re-estimated parameters are available from the authors on request.

From the above we conclude that it is important to allow for censoring. Although the choice of the upper boundary for labour supply is more or less arbitrary, the variations in predicted wages as a result of alternative upper boundaries are relatively small for variations between 75 and 100 hours. It could be argued that a labour supply of 100 hours per week (an average of 14 hours per day for seven days per week) can safely be taken as an upper limit on the possible hours of labour supply.

The estimated model can be used to impute wages for those who work 50 hours or more, by calculating the expected wage conditional on it being in between the income from wages and salaries divided by the upper bound of labour supply and the income from wages and salaries divided by 50 (the lower bound of labour supply). This would be an improvement over choosing 50 as the hours of labour supply, which would systematically overstate the wage level at higher hours of labour supply.

6 Conclusion

This paper has reported estimates of wage equations for Australian workers, using pooled data from the Surveys of Income and Housing Costs for 1994/95, 1995/96, 1996/97 and 1997/98, the most recent four years for which continuous hours information is available for each individual. The results for the wage equations are as expected, with education, work experience and age increasing the expected wage. The process of assigning a wage rate to non-workers, as necessary in the context of labour supply analysis, was examined with special attention given to dealing with the situation where the wage equation includes variables that are not available for the unemployed (such as occupation and industry).

Additionally, wage information on individuals, who work more than 49 hours per week and for whom the exact number of hours is therefore unknown in the SIHC, is included as a range rather than approximated by an “exact” value. Creedy et al. (2001) choose 50 hours as the labour supply for those who worked more than 49 hours. This results in an overestimation of the wage rates.

Allowing for the censoring of labour supply makes a clear difference in the predicted wage particularly for married men, who are the group most often observed to work long hours.

The approach taken here could easily be incorporated in a simultaneous wage and labour supply model. For labour supply models where the wage equation is estimated separately, the approach set out in this paper can be used to impute wages for the non-workers and for those who work 50 hours or more. The expected wage for the latter group is calculated by conditioning on the observed range of wage rates, which can be attained.

Appendix: Summary Statistics

Summary statistics for the various demographic groups are shown in Tables A.2 and A.3. Many variables are dummy variables taking (0,1) values, the tables show the proportions in each category for these variables. The samples used in the selection equations and the wage equations are different, so the summary statistics for each are reported in a separate table.

Information about the last full-time job of those unemployed in June 1995, taken from the Labour Force Survey (ABS Catalogue, number 6203, Table 28), were used to construct the proportions given in Table A.4.
